

Getting Started

Everyone go around and say your name, just in case someone forgot.

Think of a big word with at least three syllables, such as “solitary” or “conundrum” or “ominous”. Write it down privately so that you can show everyone at the end. Try to use it as many times as you can during today’s discussion, but in ways that don’t give away that it’s your big word. At the end, your group will try to guess each person’s big word. Whoever uses their big word the most times (and at least twice) without their group guessing it wins. (You win nothing; it’s just a game.)

Someone from your group should join [Discord](#).

To get help from a TA, send a message to the `discuss-queue` channel with the `@discuss` tag and your discussion group number.

If you have only 1 or 2 people in your group, you can join the other group in the room with you.

The most common suggestion from last discussion was to add some hints, so we have. The second most common suggestion was to encourage more discussion and collaboration. Discuss and collaborate!

Trees

For a tree `t`: - Its root label can be any value, and `label(t)` returns it. - Its branches are trees, and `branches(t)` returns a list of branches. - An identical tree can be constructed with `tree(label(t), branches(t))`. - You can call functions that take trees as arguments, such as `is_leaf(t)`. - That’s how you work with trees. No `t == x` or `t[0]` or `x in t` or `list(t)`, etc. - There’s no way to change a tree (that doesn’t violate an abstraction barrier).

Here’s an example tree `t1`, for which its branch `branches(t1)[1]` is `t2`.

```
t2 = tree(5, [tree(6), tree(7)])  
t1 = tree(3, [tree(4), t2])
```

Example Tree

A path is a sequence of trees in which each is the parent of the next.

You don’t need to know how `tree`, `label`, and `branches` are implemented in order to use them correctly, but here is the implementation from lecture.

```

def tree(label, branches=[]):
    for branch in branches:
        assert is_tree(branch), 'branches must be trees'
    return [label] + list(branches)

def label(tree):
    return tree[0]

def branches(tree):
    return tree[1:]

def is_leaf(tree):
    return not branches(tree)

def is_tree(tree):
    if type(tree) != list or len(tree) < 1:
        return False
    for branch in branches(tree):
        if not is_tree(branch):
            return False
    return True

```

Q1: Warm Up

What does this expression evaluate to?

```
label(min(branches(max([t1, t2], key=label)), key=label))
```

Solution

6: `max([t1, t2], key=label)` evaluates to the `t2` tree because its label 5 is larger than `t1`'s label 3. Among `t2`'s branches (which are leaves), the left one labeled 6 has a smaller label.

How convoluted! (That's a big word.) Talk about it with your group. When you all agree, post your answer to your group's Discord [channel's text chat](#).

If no one in your group knows how `key` functions work with `max` and `min`, here's a quick refresher.

`max(s, key=f)` returns the item `x` in `s` for which `f(x)` is largest.

```

>>> s = [-3, -5, -4, -1, -2]
>>> max(s)
-1
>>> max(s, key=abs)
-5
>>> max([abs(x) for x in s])
5

```

Therefore, `max([t1, t2], key=label)` returns the tree with the largest label, in this case `t2`.

In case you're wondering, this expression does not violate an abstraction barrier. `[t1, t2]` and `branches(t)` are both lists (not trees), and so it's fine to call `min` and `max` on them.

Q2: Has Path

Implement `has_path`, which takes a tree `t` and a list `p`. It returns whether there is a path from the root of `t` with labels `p`. For example, `t1` has a path from its root with labels `[3, 5, 6]` but not `[3, 4, 6]` or `[5, 6]`.

Important: Before trying to implement this function, discuss these questions from lecture about the recursive call of a tree processing function: - What recursive calls will you make? - What type of values do they return? - What do the possible return values mean? - How can you use those return values to complete your implementation?

If you get stuck, you can view our answers to these questions by clicking the hint button below, but *please* don't do that until your whole group agrees.

What recursive calls will you make?

As you usual, you will call `has_path` on each branch `b`. You'll make this call after comparing `p[0]` to `label(t)`, and so the second argument to `has_path` will be the rest of `p`: `has_path(b, p[1:])`.

What type of values do they return?

`has_path` always returns a `bool` value: `True` or `False`.

What do the possible return values mean?

If `has_path(b, p[1:])` returns `True`, then there is a path through branch `b` for which `p[1:]` are the node labels.

How can you use those return values to complete your implementation?

If you have already checked that `label(t)` is equal to `p[0]`, then a `True` return value means there is a path through `t` with labels `p` using that branch `b`. A `False` value means there is no path through that branch, but there might be path through a different branch.

```

def has_path(t, p):
    """Return whether tree t has a path from the root with labels p.

    >>> t2 = tree(5, [tree(6), tree(7)])
    >>> t1 = tree(3, [tree(4), t2])
    >>> has_path(t1, [5, 6])          # This path is not from the root of t1
    False
    >>> has_path(t2, [5, 6])          # This path is from the root of t2
    True
    >>> has_path(t1, [3, 5])          # This path does not go to a leaf, but that's ok
    True
    >>> has_path(t1, [3, 5, 6])       # This path goes to a leaf
    True
    >>> has_path(t1, [3, 4, 5, 6])    # There is no path with these labels
    False
    """
    if p == [label(t)]:
        return True
    elif label(t) != p[0]:
        return False
    else:
        for b in branches(t):
            if has_path(b, p[1:]):
                return True
        return False

```

The base case expression `p == [label(t)]` checks two things: that `p` has one item and that the item is equal to `label(t)`. Longer expressions (that don't fit the template) would also work, such as `if len(p) == 1 and p[0] == label(t)`.

The recursive case expresses that if a path through some branch `b` is labeled `p[1:]`, then there is a path through `t` labeled `p`.

If your group needs some guidance, you can click on the hints below, but please talk with your group first before reading the hints.

The first base case should check whether `p` is a list of length one with the label of `t` as its only element. The second base case should check if the first element of `p` matches the label of `t`.

When entering the recursive case, your code should already have checked that `p[0]` is equal to `label(t)`, and so all that's left to check is that `p[1:]` contains the labels in a path through one of the branches.

```

for ____:
    if ____:
        return True
return False

```

Your group is always welcome to ask for help in the [#discuss-queue](#) channel.

Q3: Find Path

Implement `find_path`, which takes a tree `t` with unique labels and a value `x`. It returns a list containing the labels of the nodes along a path from the root of `t` to a node labeled `x`.

If `x` is not a label in `t`, return `None`. Assume that the labels of `t` are unique.

First talk through how to make and use the recursive call. (Try it yourselves; don't just click the hint button. That's how you learn.)

What recursive calls will you make?

`find_path(b, x)` on each branch `b`.

What type of values do they return?

Each recursive call will either return `None` or a non-empty list of node labels.

What do the possible return values mean?

If `find_path(b, x)` returns `None`, then `x` does not appear in `b`. If `find_path(b, x)` returns a list, then it contains the node labels for a path through `b` that ends with the node labeled `x`.

How can you use those return values to complete your implementation?

If a list is returned, then it contains all of the labels in the path except `label(t)`, which must be placed at the front.

```
def find_path(t, x):
    """
    >>> t2 = tree(5, [tree(6), tree(7)])
    >>> t1 = tree(3, [tree(4), t2])
    >>> find_path(t1, 5)
    [3, 5]
    >>> find_path(t1, 4)
    [3, 4]
    >>> find_path(t1, 6)
    [3, 5, 6]
    >>> find_path(t2, 6)
    [5, 6]
    >>> print(find_path(t1, 2))
    None
    """
    if label(t) == x:
        return [label(t)]
    for b in branches(t):
        path = find_path(b, x)
        if path:
            return [label(t)] + path
    return None
```

The base case return value `[label(t)]` creates a one-element list of the labels along a path that starts at the root of `t` and also ends there, since the root is labeled `x`.

The assignment `path = find_path(b, x)` allows the return value of this recursive call to be used twice: once to check if it's `None` (which is a false value) and again to build a longer list.

The expression `[label(t)] + path` for a tree `t` and list `path` creates a longer list that starts with the label of `t` and continues with the elements of `path`.

Please don't view the hints until you've discussed with your group and can't make progress.

If `x` is the label of `t`, then return a list with one element that contains the label of `t`.

Assign `path` to the result of a recursive call to `find_path(b, x)` so that you can both check whether it's `None` and extend it if it's a list.

For a list `path` and a value `v`, the expression `[v] + path` creates a longer list that starts with `v` and then has the elements of `path`.

Description Time! When your group has completed this question, it's time to describe why this function does not have a base case that uses `is_leaf`. Come up with an explanation as a group, pick someone to present your answer, and then send a message to the discuss-queue channel with the @discuss tag, your discussion group number, and the message "Found it!" and a member of the course staff will join your voice channel to hear your description and give feedback.

Challenge Question

If you have time, work on this more challenging tree processing problem as a group. When there's only 5 minutes left, skip ahead to the Document the Occasion section.

The `print_tree` function from the lecture videos (used in the doctests below) prints all of the labels of a tree.

```
>>> print_tree(t1)
3
  4
  5
    6
    7
```

```

def print_tree(t, indent=0):
    """Print a representation of this tree in which
    each label is indented by two spaces times its
    depth from the root.

    >>> print_tree(tree(1))
    1
    >>> print_tree(tree(1, [tree(2)]))
    1
      2
    >>> print_tree(fib_tree(4))
    3
      1
        0
        1
      2
        1
        1
          0
          1
    """
    print('  ' * indent + str(label(t)))
    for b in branches(t):
        print_tree(b, indent + 1)

def fib_tree(n):
    """Construct a Fibonacci tree.

    >>> fib_tree(5)
    [5, [2, [1], [1, [0], [1]]], [3, [1, [0], [1]], [2, [1], [1, [0], [1]]]]
    """
    if n == 0 or n == 1:
        return tree(n)
    else:
        left = fib_tree(n-2)
        right = fib_tree(n-1)
        fib_n = label(left) + label(right)
        return tree(fib_n, [left, right])

```

Q4: Make Path

Implement `make_path`, which takes a tree `t` with unique labels and a list `p` that starts with the root label of `t`. It returns the tree `u` with the fewest nodes for which `has_path(u, p)` returns `True` **and** `has_path(u, q)` returns `True` for all lists `q` for which `has_path(t, q)` returns `True`. (That is, `u` has all the paths of `t` as well as a path with labels `p`.)

Each node in `u` that does not correspond to a node in `t` should be placed last in its parent's list of branches. Assume

that the labels of `t` are unique. If `has_path(t, p)`, then `make_path(t, p)` should return a tree identical (in structure and labels) to `t`.

```

def make_path(t, p):
    """Return a tree with all of the nodes of t and a path with labels p.

    >>> t2 = tree(5, [tree(6), tree(7)])
    >>> t1 = tree(3, [tree(4), t2])
    >>> make_path(t1, [3, 5, 7]) == t1
    True
    >>> print_tree(make_path(t1, [3, 8, 9, 1]))
    3
      4
      5
        6
        7
      8
      9
        1
    >>> print_tree(make_path(t1, [3, 4, 8, 9]))
    3
      4
      8
      9
      5
      6
      7
    >>> print_tree(make_path(tree(2, [tree(1), t1]), [2, 3, 5, 6, 8]))
    2
      1
      3
      4
      5
      6
      8
      7
    """
    assert p[0] == label(t), 'It is not possible to make this path'
    if len(p) == 1:
        return t
    new_branches = []
    found_p1 = False
    for b in branches(t):
        if label(b) == p[1]:
            new_branches.append(make_path(b, p[1:]))
            found_p1 = True
        else:
            new_branches.append(b)
    if not found_p1:
        new_branches.append(make_path(tree(p[1]), p[1:]))
    return tree(label(t), new_branches)

```

Note: This worksheet is a problem bank—most TAs will not cover all the problems in discussion section.

Because of the `assert`, the base case condition `len(p) == 1` is enough to confirm that `p == [label(t)]`. In this case, there are no additional nodes needed to ensure that a path labeled `p` is in `t`.

To minimize the number of nodes added to the tree, first we look for a branch that can be extended. The name `found_p1` will determine whether to add an additional branch to `new_branches` that does not correspond to a branch in `branches(t)`. Updating it to `True` when a branch is found with `label(b) == p[1]` ensures that the path is added only to this branch.

What recursive calls will you make?

`make_path(b, p[1:])` can only be called on a `b` whose label is `p[1]`. You either find such a branch or make one with `tree(p[1])`.

What type of values do they return?

The recursive call returns a tree that contains a path with labels `p[1:]`.

What do the possible return values mean?

This return value is a branch of the tree returned by `make_path(t, p)`.

How can you use those return values to complete your implementation?

Place the return value in the list of `new_branches`.

Since you've already asserted that `p[0] == label(t)`, if `p` has length 1 then `t` contains a path with labels `p`, so you can just return `t`.

If `p[1]` is a label of a branch, then a path should be made through that branch. Otherwise, a new branch must be made.

Search through each branch to find one whose label is `p[1]`, then append the result of a recursive call on that branch to `new_branches`.

In the case that no branch has label `p[1]`, create a new branch with `tree(p[1])`, use `make_path` to build the rest of the branch, and append that result to `new_branches`.

Document the Occasion

For each person, the rest of the group should try to guess their *big word* (from the Getting Started section). The group only gets one guess. After they guess, reveal your *big word* and how many times you used it during discussion. Post the winning word (the one that was not guessed but used the most times) in your group's [channel's text chat](#).

Please all fill out the [attendance form](#) (one submission per person per week).
